Abstract. In this article, hybrid parallel bidirectional sieve is implemented by SMP Cluster, the individual computational units joined together by the communication network, are usually shared-memory systems with one or more multicore processor. To high-efficiency optimization, we propose average divide data into nodes, generating double-ended queues (deque) for sieve that are able to exploit dual-cores simultaneously start sifting out primes from the head and tail. And each node create a FIFO queue as dynamic data buffer to ache temporary data from another nodes send to. The approach obtains huge speedup and efficiency on SMP Cluster.

Keywords: hybrid parallel, HPC, SMP Cluster, sieve

1 Introduction

Research into questions involving primes continues today, partly driven by the importance of primes in modern cryptography. As our computational power increases, researcher often pays more attention to Data analysis, Climate modeling, Protein folding, Drug discovery etc. We can also exploit multicores to efficiency solve some problem in the field of number theory.

M.Aigner and G.M.Ziegler [1] presented six quite different proofs of the infinitude of primes. Mills[2] has shown that there is a constant Θ such that the function $f(n) = \lceil \Theta^{3^n} \rceil$ generates only primes. The sieve of Eratosthenes-Legendre [3] [4] is an ancient algorithm for finding all prime numbers up to any given limit. In number theory, tests distinguishing between primes and composite integers will be crucial. The most basic primality test is trial division, which tells us that integer n is prime if and only if it is not divisible by any prime not exceeding $\sqrt{n}$.

The computational complexity of algorithms for determining whether an integer is prime is measured in terms of the number of binary digits in the integer. The algorithm using trial divisions to determine whether an integer n is prime is exponential in terms of the number of binary digits of n , or in terms of $\log_2 n$, because $\sqrt{n} = 2^{\log_2 n / 2}$.

As n gets large, an algorithm with exponential complexity quickly becomes impractical. Leonard Adleman, Carl Pomerance, and Robert Rumely [5] [6] developed an algorithm that can prove an integer is prime using $(\log n)^{c \log \log \log n}$

nit operations, where c is a constant. In 2002, M. Agrawal, N. Kayal, and N. Saxena [7], announced that they had found an algorithm PRIMES is in P that can produce a certificate of primality for an integer n using $O((\log n)^{12})$ bit operations.

Karl Friedrich Gauss conjectured that $\pi(x)$ increases at the same rate as the functions $\frac{x}{\log x}$ and $Li(x) = \int_2^x \frac{dt}{\log t}$. And the Prime Number Theorem that the ratio of $\pi(x)$ to $\frac{x}{\log x}$ approaches 1 as x grows without bound. One way [11] to evaluate $\pi(x)$ only $O(x^{\frac{3}{5}+e})$ bit operations without finding all the primes less than x is to use a counting argument based on the sieve of Eratosthenes.

In this paper, Hybrid parallel bidirectional sieve based on SMP Cluster is proposed to improve efficient and speedup. The result is proved to be effective by MPI and OpenMP [8] [9] [10]. With Hybrid parallel, it has far-reaching significance in cryptography.

2 Communication and Optimization

ILP and TLP provide parallelism at a very low level, they are typically controlled by the processor and the operating system, and isn't directly controlled by the programmer. Parallel hardware is often classified using Flynn's taxonomy, which distinguished between the number of instruction streams and the number of data streams a system can handle. A von Neumann system is classified as SISD. Vector processors and graphics processing units (GPU) are often classified as SIMD. MIMD execute multiple independent instruction streams, each of which can have its own data stream. Shared-memory or distributed-memory is typically MIMD. And most of the lager MIMD systems are hybrid systems (Fig.1) in which a number of relatively small share-memory are connected by an interconnection network. In such systems, the individual shared-memory systems are sometimes called nodes.

Fig. 1. SMP Cluster Architecture.

2.1 Interconnection networks

Currently the two most widely used interconnects on shared-memory systems are buses and crossbars [15]. The key characteristic of a bus is that the communication wires are shared by the devices that are connected to it. Buses have the virtue of low cost and flexibility. Crossbars (Fig.2) allow simultaneous communication among different devices, so they are much faster than buses. But the cost of the switches and links is relatively high.

Distributed-memory interconnects are often divided into two groups: direct interconnects and indirect interconnects. One measure of "number of simultaneous communications" or "connectivity" is bisection width. To understand this measure, imagine that the parallel system is divided into two halves, and each half contains half of the processors or nodes. An alternate way of computing the bisection width is to remove the minimum number of links needed to split the set of nodes into two equal halves.

Fig. 2. Shared-memory system simultaneous memory access

The hypercube (Fig.3) is a highly connected direct interconnect that has been used in actual system. A hypercube of dimension d has $p = 2^d$ nodes, and a switch in a d -dimensional hypercube is directly connected to a processor and d switches. The bisection width of a hypercube is $\frac{p}{2}$. The switches support $1 + d = 1 + \log_2 p$ wires. The hypercube is more powerful and expensive to construct.

The crossbar and the omega network are relatively simple examples of indirect networks. The omega network (Fig.4) is less expensive than crossbar. The omega network uses $\frac{1}{2}p \log_2(p)$ of the 2×2 crossbar switches, so it uses a total of $2p \log_2(p)$ switches, while the crossbar users p^2 .

Fig. 3. (a) two-dimensional hypercube (b) three-dimensional hypercube (c) four-dimensional hypercube

2.2 Hybrid Parallelism

We define the speedup of a parallel program to be $S = \frac{T_{serial}}{T_{parallel}}$. Then linear speedup has $S = P_{cores}$, this value, $\frac{S}{P}$, is sometimes called the efficiency of the parallel program as follows:

$$E = \frac{S}{P} = \frac{\frac{T_{serial}}{T_{parallel}}}{P} \quad (1)$$

Back in the 1960s, Gene Amdahl [13] that's become as Amdahl's Law:

$$S_{overall} = \frac{1}{(1 - f) + \frac{f}{s}} \quad (2)$$

It means that unless virtually all of a serial program is parallelized, the possible speedup is going to be very limited-regardless of the number of cores available. A more mathematical version of this statement is known as Gustafson's Law [14].

Unfortunately, there are several mismatch problem between the (hybrid) programming schemes and the hybrid hardware architecture. Often, one can see in publications, that applications may or may not benefit from hybrid programming depending on some application parameters, e.g., in [16][17][18] [19].

Polf Rabenseifner analyses strategies to overcome typical drawbacks of this easily usable programming scheme on systems with weaker inter-connects [20]. Best performance can be achieved with overlapping communication and computation, but this scheme is lacking in ease of use. Often, hybrid MPI + OpenMP programming denotes a programming style with OpenMP shared memory parallelization inside the MPI processes (i.e., each MPI process itself has several OpenMP threads) and communication with MPI between the MPI processes, but only outside of parallel regions.

This hybrid programming scheme will be named materonly in the following classification, which is based on the question, when and by which thread(s) the messages are sent between the MPI processes:

- . Pure MPI

- . Hybrid MPI + OpenMP
- . Overlapping communication and computation
- . Pure OpenMP

Overlapping of communication and computation is a chance for an optimal usage of the application itself, in the OpenMP parallelization and in the load balancing. It requires a coarse-grained and thread-rank-based OpenMP parallelization, the separation of halo-based computation from the computation that can be overlapped with communication, and the threads with different tasks must be load balanced. Advantages of the overlapping scheme are:

- . the problem that one CPU may not achieve the inter-node bandwidth is no longer relevant as long as there is enough computational work that can be overlapped with the communication
- . the saturation problem is solved as long as not more CPUs communicate in parallel than necessary to achieve the inter-node bandwidth
- . the sleeping threads problem is solved as long as all computation and communication is load balanced among the threads.

Fig. 4. (a) Crossbar (b) omega network

3 Bidirectional Sieve Model

Foster's methodology [12] provides an outline of steps include

- . Partitioning.
- . Communication.
- . Agglomeration or aggregation
- . Mapping for parallel programming

3.1 Algorithm Design

The sieve of Eratosthenes does so by iteratively marking as composite the multiples of each prime, starting with the multiples of 2 [4]. We can exploit and improve the sieve of Eratosthenes based on SMP Cluster (Fig. 5). Assume that there are some disorder integers which the scale of n , and when each node sieve the integers in the block that the scale of k , it could achieve high-efficiency optimization. We conjectured that the SMP Cluster requires at least N nodes. The formula as follows:

$$N = \frac{n}{k} + (n \bmod k) \ \& \ 1 \quad (3)$$

And each node generate one deque and do with dual-cores. One core is located in the head of the deque. On the contrary, the other one is located in the tail of the deque. It's easy to deduction the formula about the amount of cores(C_{cores}) and deque(D_{deque}):

$$C_{cores} = D_{deque} = 2N \quad (4)$$

There is another point that's worth considering. In most cases, the scale of node N is not exactly equal k . We can deal with the state as follows Alg.1:

Algorithm 1 the scale of node N^{th}

Require: K denote that the currency scale of node N^{th}

Ensure: k denote that the general scale of node

if $0 \leq K \leq \frac{k}{2}$ **then**

Node N assign single core to right or left sieve

else

Node N assign dual-cores to simultaneous bidirectional sieve

end if

And its flow diagram is shown in Fig.6.

3.2 Primality Testing : Non-deterministic

Primality testing of a number is perhaps the most common problem concerning number theory. The problem of detecting whether a given number is a prime number has been studied extensively but nonetheless, it turns out that all the deterministic algorithms for this problem are too slow to be used in real life situations and the better ones amongst them are tedious to code. But, there are some

Fig. 5. Construct Bidirectional Sieve

probabilistic methods which are very fast and very easy to code. Moreover, the probability of getting a wrong result with these algorithms is so slow that it can be neglected in normal situations.

All the algorithms which we are going to discuss will require you to efficiently compute $(a^b) \bmod c$ (where a, b, c are non-negative integers). A straightforward algorithm to do the task can be to iteratively multiply the result with a and take the remainder with c at each step, this algorithm takes $O(b)$ time and is not very useful in practice. We can do it $O(\log b)$ by using what is called as exponentiation by squaring as follows:

$$f(n) = \begin{cases} (a^2)^{\frac{b}{2}}, & \text{if } b \text{ is even and } b > 0 \\ a(a^2)^{\frac{b-1}{2}}, & \text{if } b \text{ is odd} \\ 1, & \text{if } b = 0 \end{cases}$$

Pierre de Fermat first stated the Fermat's Little Theorem in a letter dated October 18, 1640, to his friend and confidant Frénicle de Bessy as the following [7]:

$$a^p = a \pmod{p} \quad (5)$$

or alternatively:

$$a^{p-1} = 1 \pmod{p} \quad (6)$$

According to Fermat's Little Theorem [7], if p is a prime number and a is a positive integer less than p ($a < p$), and then calculate $a^{p-1} \bmod p$. If the result is not 1, then by Fermat's Little Theorem p cannot be prime. The more iterations we do, the higher is the probability that our result is correct.

Fig. 6. High-level flow diagram of hybrid parallel bidirectional Sieve

Algorithm 2 modulo(a,b,c) : Exponentiating by squaring to $(a^b) \bmod c$

Require: $x = 1, y = a$

Ensure: $(a^b) \bmod c$

```

while  $b > 0$  do
  if  $b \& 1$  then
     $x = (x * y) \bmod c$ 
  end if
   $y = (y * y) \bmod c$ 
   $b \gg= 1$ 
end while
return  $x \bmod c$ 

```

Algorithm 3 Fermat(p,iterations) : Fermat's primality test

```

if  $p = 1$  then
  return false
end if
for  $i := 1$  to iterations do
   $a = \text{rand}() \bmod (p - 1) + 1$ 
  if modulo(a,p-1,p) != 1 (Alg.2) then
    return false
  end if
end for
return true

```

Though Fermat is highly accurate in practice there are certain composite numbers p known as Carmichael numbers for which all values of $a < p$ for which $\gcd(a, p) = 1, (a^{p-1}) \bmod p = 1$. And in that case, the Fermat's test will return wrong result with very high probability. Out of the Carmichael numbers less than 10^{16} , about 95% of them are divisible by primes < 1000 . However, there are other improved primality tests which don't have this flaw as Fermat's (e.g. Rabin-Miller test [21][22], Solovay-Strassen test [23]).

4 Performance Analysis

Different programming schemes on clusters of SMPs show different performance benefits or penalties in this paper. Fig.7 summarizes the result of hybrid parallel bidirectional sieve. It's obvious that nodes communication would waste most of time when data scale is tiny. Even it's slower than general method. However, if there are hyper-data scale, hybrid parallel show huge efficiency and optimization. Indeed, sometimes the waste of communication could be neglected. In that case, multicores parallelism is effective approach to solve some problem in number theory.

To achieve an optimal usage of the hardware, one can also try to use the idling CPU's for other applications, especially low-priority single-threaded or multi-

Fig. 7. statistics and analysis hybrid parallel bidirectional sieve with general method

threaded non-MPI application if the parallel high-priority hybrid application does not use the total memory of the SMP nodes.

5 Conclusion

In this study we have shown that hybrid parallel on SMP cluster is an applicable method to implement bidirectional sieve. The analysis demonstrated that even hybrid parallel bidirectional sieve is efficiency and optimization solution.

As our computational power increases, Most HPC system are clusters of shared memory nodes. Parallel programming must combine the distributed memory parallelization on the node inter-connect with shared memory parallelization inside of each node. And Each parallel programming schema on hybrid architecture has one or more significant drawbacks (e.g. sleeping-thread and saturation problem). However, Hybrid parallel also has far-reaching significance in many fields (e.g. Cryptography, Data analysis, Climate modeling, Protein folding, Drug discovery).

We believe that hybrid parallel bidirectional sieve can be properly modeled using techniques from number theory and this article is just an early trial of using hybrid parallelism to improve speedup and efficiency.
